ABSTRACT

Objective: To study the prevalence of silent cerebral infarction in Type II diabetes mellitus.

Materials and Methods: The study was a prospective study on 80 patients recruited from neurology, endocrine outpatient clinics. Patients were type II diabetics as described by the American Diabetes Association, 2011 criteria. All patients underwent full metabolic profiles to diagnose diabetes mellitus and MRI brain scans to detect cerebral infarction.

Results: Silent cerebral infarctions were detected in 60% of patients (48/80 patients) predominately along periventricular white matter area and subcortical areas (Basal ganglia, Thalamus).

Conclusion: Asymptomatic Type II diabetes mellitus patients could have vascular cerebral changes without neurological symptoms. MRI brain scans could be recommended as routine diagnosis (if possible) for early cerebral infarct detection in type II diabetic patients

Key words: Prevalence, Silent Brain Infarction, Diabetes Mellitus
INTRODUCTION

Type 2 Diabetes mellitus is a metabolic disorder which is characterized by hyperglycemia because of insulin resistance and deficiency of insulin. The diagnosis is in contrast to type 1 diabetes mellitus, in which there is an absolute insulin deficiency due to breakdown of islet cells in the pancreas. The classic symptoms are polyuria, polydipsia, and increased appetite. Highly sensitive techniques for brain imaging like MRI can detect potential abnormal findings. Such findings include lesions with an appearance typical of infarction; when these appear in persons without a history compatible with stroke, they are often referred to as “silent infarcts”. The strong relationship of “silent infarcts” with age and other stroke risk factors suggests that they themselves may be risk factors or even manifestations of clinically important cerebrovascular disease.

Silent cerebral infarctions (SCIs), also termed covert infarcts or simply MRI infarcts. These are parenchymal lesions that have the MRI characteristics of previous infarcts but have not been associated with clinical signs or symptoms of a stroke. Fischer described them first in a cohort of 114 subjects who came for autopsy. He found 88 brains had at least 1 lacunae in the absence of clinical deficits or a stroke history.

The prevalence of SCI on MRI scans, in recent studies has ranged from 5.84% to 28%. Reasons for this variation may be due to differences in the definition of SCI, in MRI techniques, age, sex, and risk factor profile of the population being studied.

MATERIALS AND METHODS

The prospective study was conducted from April 2013 to December 2013 on 80 patients from neurology, endocrine and internal medicine outpatient clinics. Patients were informed about research objectives and benefits. Written consents were obtained and signed and approved by the local ethics committee.

Inclusion criteria: Age: 20 - 65 years. Males and females were included. The inclusion criteria for diabetes mellitus: any patient who was a known diabetic on medication. Criteria for diagnosis of Diabetes mellitus (type II):
- Symptoms of diabetes plus random blood glucose concentration > 200 mg/dl or
- Fasting plasma glucose > 126 mg/dl or
- HbA1C > 6.5% or
- Two hour plasma glucose >200 mg/dl during an oral glucose tolerance test

Exclusion criteria: includes, previous stroke, any other metabolic conditions to be excluded (i.e. Diabetes complicated by renal failure).

Image Acquisition

All imaging studies were performed on Siemens MRI-scanner MAGNETOM Aera, 1.5 Tesla T1 and T2-weighted FSE images with 5 mm thick sections, 256 × 256 matrix, FOV 20 cm, TR 5650, TE 102, and 16 echo train length. The MRI examinations included FLAIR, T2- and
T1-weighted spin-echo images with 5-mm thickness and zero gaps and oriented parallel to the anterior-posterior commissure line.

Infarcts by MRI were defined as lesions with abnormal signal in a vascular distribution and no mass effect. Infarcts of the cortical gray matter and deep nuclear regions and capsule were defined as lesions bright on FLAIR and T2-weighted images compared with normal gray matter and isodense or hypodense on T1-weighted images. Infarcts in the white matter were also bright on spin-density and T2-weighted images but in addition were hypointense on T1-weighted images.

RESULTS
Demographic: With regards to gender, 60 patients (75%) were male and 20 patients (25%) were female. The mean group age was 42.4 years. Criteria and distribution of MRI brain lesions are described in Table 1, Figure 1, Figure 2 and Figure 3.

From the table we noticed that 50% of cases (24/48) had silent cerebral infarctions with periventricular white matter distribution, 33.3% (16/48) had infarcts in the basal ganglia and 16.66% had infarction in the thalamus.

Table 1. Site and distribution of silent cerebral infarction detected by MRI brain

Figure 1. A 51 years-old male patient with multiple periventricular lacunar infarctions of high FLAIR signal.
Figure 2. A 63 years old male patient with multiple head of caudate and posterior periventricular infarctions of high FLAIR signal.

Figure 3. A 61 years old female with bilateral basal ganglia foci of Infarction in anterior limb of the right internal capsule and adjacent part of caudate nucleus lesion of high T2 signal.
DISCUSSION
Silent Cerebral Infarction (SCI) is a disruption in the flow of blood to the brain (stroke). It produces symptoms so brief and mild that the person often does not become concerned or seek medical attention. The SCI is found by chance when the patient is examined by MRI (magnetic resonance imaging), often for an unrelated condition.

MRI has the advantage of lack of exposure to ionizing radiation, but it is expensive. While the availability of MRI is increasing, still there are many centers where they are not available. There are also absolute and relative contraindications to MRI, limiting its availability, such as cardiac pacemakers and certain metallic implanted substances. Although claustrophobia is common with MRI, the advent of open MRI and faster scanning time had made this a decreasing concern.

While numerous reports have documented the frequency of presumed infarctions on CT or MRI in persons with a history of (or at risk for) overt stroke, few studies have reported prevalence of such lesions in an asymptomatic community-dwelling population. The American heart association has warned that SCI may be a predisposing factor for major stroke. The significance of this research is to increase awareness of treating physicians about SCI to educate healthcare decision makers about this health problem and to highlight the extension of this problem in community at large population.

Results of our study showed that 60% of our sample had positive MRI findings at T1 and T2 and FLAIR suggestive of cerebral ischemia in asymptomatic patients with diabetes mellitus type II. This differs from the results obtained by Nakamura and his colleague who found that 20% had silent cerebral infarction. This difference could be due to differences in study design, sample size or the degree of disease progression before the MRI brain scan was conducted.

In our study we found that the lesions had certain distribution as 50% are mainly periventricular, 33.3% at basal ganglia and 16.66% at thalamus. This may explain that perforator vessels are more affected than the other cerebral vessels.

The findings suggested a relation between gender of the patient and MRI brain lesion distribution. Because it was not included in our study design we were unable to support this interpretation. Future studies should study such a relationship, if possible.

We recommend the use of MRI brain as a routine investigation in neurologically asymptomatic diabetic patients to detect early vascular ischemic changes.

CONCLUSION
Asymptomatic Type II diabetes mellitus patients could have vascular cerebral changes without neurological symptoms. MRI brain scans could be recommended as routine diagnosis (if possible) for early cerebral infarct detection in type II diabetic patients.
